m_corr = Cm_post(1,2)/prod(sqrt(diag(Cm_post)));
%{
    The uncertainty in the slope and y-intercept are 0.0483 and 0.0603,
    respectively. The off diagonal terms of the posterior model covariance
    matrix are nonzero, so these parameters are correlated (i.e. they trade-off
    with each other). The correlation coefficient here is -0.8276, which means
    that the slope and y-intercept are strongly anti-correlated. This makes
    sense because if you were to increase the y-intercept by a small ammount,

```

---

---

```

the slope would have to decrease drastically to stay fitted to the data.
%}

%q1.6
y = [0.3; 3.06; 0.44; 1.05; 2.92; 4.47; 3.38; 2.5];
Cd2 = diag([0.01,1,0.01,0.01,0.01,0.01,0.01,0.01]);

%{
    Cm_post2 =
    0.0024    -0.0026
   -0.0026     0.0042
    The uncertainty on the slope and the y-intercept are 0.049 and 0.0648,
    respectively. The correlation coefficient this time is again very negative,
    indicating an anti-correlation between the slope and y-intercept, with a
    value of -0.8103. Overall, adding in an outlier with a large uncertainty
    did not change the model by a significant amount. Through my own analysis,
    however, I tested what the effect of an outlier with a small uncertainty
    would be, and this changed the model significantly more.

%{
    The modeled structure is certainly close to the actual structure, but
    differs in a few key ways. The first is that on the right angle turn at
    (0.8,0.2), the model struggles to reproduce the slowness values. This is
    expressed in the model as having a larger spread of slowness values around
    this area, and the slowness values that do appear are much lower than the
    actual structure. The top piece of the structure, however, that occurs at
    y=0.9 is predicted very well. One reason that the right angle turn may be
    less resolved is that this area of the grid is relatively undetermined.
    That is, there are only paths passing through this location coming from 2
    stations.

%{
    The retrieved structure only differs slightly from the case where mu =
    1. If I had to state a general change, it looks like some vaues are now
    closer to the actual structure of uniform 0.2 slowness, but this is not
    always the case. The two cases are likely so similar because the data is not
    changing, only the prior information. Therefore, the model comes to roughly
    the same conclusion, since it is seeing the same data.

%q2.7
%{
    The retrieved structure becomes fuzzier as noise is added to the
    travel times. As the standard deviation approaches 1, the structure becomes
    entirely hidden by the noise. The first regions of the structure to become
    affected by noise are areas that are relatively underdetermined by crossing
    travel time paths. Areas that are more overdetermined, such as the line at
    (0.7,0.9), can be retrieved even with a little bit of noise. Too much noise
    still destroys the structure in these areas as well.

%{
    Once again, the pattern of resolution follows the density of path
    intersections. At the top of the image, where time delay paths are less
    dense, the structure is poorly resolved, but toward the bottom of the image,
    the structure is well resolved because there are many intersecting time
    delay paths. This pattern is more apparent for the smaller checkerboard
    size, but it also appears in the large checkerboard size.
